#### Abstract

Rhubarb is an important Traditional Chinese Medicine. However, the wild resource has been declining. In order to design appropriate conservation methods for the official species across their natural distributions, it is important to characterize their genetic diversity. Here, we describe the development of 10 new microsatellite loci for AC/TG/CCA in Rheum tanguticum. The microsatellites were enriched using the combined biotin capture method. The polymorphism of each locus was further assessed in 12 individuals from four geographically distinct populations of this species. The number of alleles ranged from three to seven and the expected heterozygosity ranged from 0.53 to 0.73 . All markers have been checked in the other three species in the genus and two of them together comprise the official medicinal rhubarb resource with R. tanguticum. These microsatellite markers could provide a useful tool for genetic and conservation studies of the rhubarb species.

Keywords Rhubarb - Rheum tanguticum - Microsatellite markers - Genetic diversity • Conservation

Rhubarb (Rheum) is known, in China, as the 'lord' or 'king of herbs'. It is a very important Traditional Chinese Medicine, commonly used for the treatment of constipa-

[^0]tion, diarrhea, jaundice, etc (Yang et al. 2001). Three closely related species (R. palmatum L., R. tanguticum Maxim. ex Balf. and R. officinale Baill) are officially regarded as medicinal plants in China (Wang et al. 2005). Because of excessive exploitation, the wild sources of these species decrease annually and they are now classified as endangered (Yang et al. 2001). To design effective conservation and recovery strategies, it is necessary to have available basic genetic information about these species. In this paper we describe the development of 10 polymorphic microsatellite loci in $R$. tanguticum. These are potential tools for investigating the genetic structures of rhubarb.

Genomic DNA was extracted from the dried leaves by a modified cetyltrimethyl ammonium bromide (CTAB) method (Zhou et al. 1999). About 500 ng genomic DNA was completely digested with a restriction enzyme RsaI (NEB), and ligated to SuperSNX linkers as described by Hauswaldt and Glenn (2003). For enrichment, the ligation products were hybridized with an oligonucleotide combination of $5^{\prime}$-biotinylated probes $(\mathrm{AC})_{15},(\mathrm{TG})_{15}$ and $(\mathrm{CCA})_{10}$ in $50 \mu \mathrm{l}$ hybridization solution ( $2 \times \mathrm{SSC}, 1 \mu \mathrm{~mol} / \mathrm{l}$ probe and $10 \mu \mathrm{l}$ ligation products ) as follows: an initial 5 min at $95^{\circ} \mathrm{C}$, then a rapid cooling to $70^{\circ} \mathrm{C}$, followed by $0.2^{\circ} \mathrm{C}$ incremental decreases every 5 s for 99 cycles, and maintenance at $50^{\circ} \mathrm{C}$ for 10 min ; then decreases of $0.5^{\circ} \mathrm{C}$ every 5 s for 20 cycles, and finally rapid cooling to $15^{\circ} \mathrm{C}$. The DNA hybridized to the probe was captured by strep-tavidin-coated magnetic beads at $37^{\circ} \mathrm{C}$ for 1 h , followed by two washing steps; each including two washes with washing solution $\mathrm{I}(2 \times \mathrm{SSC}, 0.1 \% \mathrm{SDS})$ for 2 min at room temperature and four washes with washing solution II ( $1 \times$ SSC, $0.1 \%$ SDS) for 2 min at $40^{\circ} \mathrm{C}, 50^{\circ} \mathrm{C}, 45^{\circ} \mathrm{C}, 45^{\circ} \mathrm{C}$ in turn. Captured DNA was recovered by polymerase chain PCR with SuperSNX-f ( $5^{\prime}$-GTTTAAGGCCTAGCTAG-CAGAATC- $3^{\prime}$ ) as follows: 2 min at $94^{\circ} \mathrm{C}$; 30 cycles of

Ta, annealing temperature of primer pair; N , number of individuals genotyped; Ho: Observed heterozygosity; $\mathrm{H}_{\mathrm{E}}$, Expected heterozygosity
$94^{\circ} \mathrm{C}$ for $20 \mathrm{~s}, 60^{\circ} \mathrm{C}$ for $20 \mathrm{~s}, 72^{\circ} \mathrm{C}$ for 90 s ; followed by 5 min at $72^{\circ} \mathrm{C}$. The PCR products, after purification using a TIANquick Mini Purification Kit (TIANGEN), were cloned into a pmD18-T vector (Takara) according to the manufacturer's instructions, and propagated in the Top10 strain of E. coli. Positive clones were harvested and cultured. Plasmid DNA was extracted using a U-gene Plasmid Moni Kit (U-gene). Each clone, 300-700 bp long as determined by PCR using universal M13 primers, was sequenced to verify the presence of microsatellites and to characterize flanking regions for primer design using a 3130xl Genetic Analyzer. The sequences containing motifs repeating more than five times were regarded as microsatellites.

A total of 26 sequences were found to contain simple sequence repeats. Primer pairs for amplification of the microsatellite regions were designed on the basis of the sequences flanking them using the Primer 5.0 (Clarke and Gorley 2001). To analyze the genetic polymorphism of the identified microsatellite loci, 12 individuals collected from four wild populations were used for genotyping. The amplification was performed in $20 \mu \mathrm{l}$ of a reaction mixture containing 10 ng of genomic DNA, 0.3 mM of each dNTP, $0.3 \mu \mathrm{M}$ of each primer, $2 \mu \mathrm{l}$ Taq buffer and 0.5 unit of Taq polymerase (Takara) using a PTC-200 thermal cycler (MJ Research). Amplifications used an initial denaturation of 3 min at $94^{\circ} \mathrm{C}$, followed by 35 cycles of denaturation for 40 s at $94^{\circ} \mathrm{C}$, annealing for 40 s at $47-52^{\circ} \mathrm{C}$ and 90 s at

[^1]$72^{\circ} \mathrm{C}$, and a final extension of 4 min at $72^{\circ} \mathrm{C}$. The PCR products were resolved on $6.5 \%$ polyacrylamide denaturing gel and visualized by silver staining. The band size was determined using a 10 bp DNA ladder (Invitrogen) as the reference.

Preliminary population genetics analyses were performed using GENEPOP version 3.4 (http://wbiomed.curtin.edu.au/genepop/) (Raymond and Rousset 1995). In total, 16 out of the 26 sequences comprised a single-locus, and the other 10 produced polymorphic banding patterns (Table 1). These 10 polymorphic loci had three to seven alleles per locus and the observed heterozygosity ranged from 0.32 to 0.47 . For each locus, the expected heterozygosity was always significantly higher than the observed heterozygosity $(P<0.05)$. No significant genotypic disequilibrium was detected for any pair of loci. As shown in Table 1, the size of the PCR products of these alleles exceeded 20 bp in most loci. The alleles were sequenced and it was confirmed that they were the target sequence.

Cross-priming tests were performed in the other three species, R. palmatum, R. officinale and R. pumilum, using two individuals of each species (Table 2). Nine loci were successfully amplified in $R$. palmatum, seven in R. officinale and five in $R$. pumilum. These polymorphic microsatellite loci could be useful for assessing the genetic
structure of the wild populations of the three official species (R. tanguticum, R. palmatum and R. officinale).
